

# Algorithmic Game Theory

## Auction theory in practice

Vangelis Markakis  
[markakis@gmail.com](mailto:markakis@gmail.com)

# Allocation rules and truthful mechanisms

- We recall first some definitions we saw in previous lectures
- Consider a mechanism with allocation rule  $\mathbf{x}$
- Definition: An allocation rule is **monotone** if for every  $i$ , and every profile  $\mathbf{b}_{-i}$ , the allocation  $x_i(z, \mathbf{b}_{-i})$  to  $i$  is non-decreasing in  $z$ 
  - i.e., bidding higher can only get you more stuff

[Myerson '81]

- Theorem: For every single-parameter environment,
  - An allocation rule  $\mathbf{x}$  can be turned into a truthful mechanism if and only if it is monotone
  - If  $\mathbf{x}$  is monotone, then there is a unique payment rule  $\mathbf{p}$ , so that  $(\mathbf{x}, \mathbf{p})$  is a truthful mechanism

# Myerson's lemma and payment formula

- For the payment rule, we need to look for each bidder at the allocation function  $x_i(z, \mathbf{b}_{-i})$
- For the single-item truthful auction:
  - Fix  $\mathbf{b}_{-i}$  and let  $b^* = \max_{j \neq i} b_j$

## Facts:

- For any fixed  $\mathbf{b}_{-i}$ , the allocation function is piecewise linear with 1 jump
- The Vickrey payment is precisely the value at which the jump happens
- The jump changes the allocation from 0 to 1 unit

# Myerson's lemma and payment formula

For most scenarios of interest

- The allocation is piecewise linear with multiple jumps
- The jump determines how many extra units the bidder wins

- Suppose bidder  $i$  bids  $b_i$
- Look at the jumps of  $x_i(z, b_{-i})$  in the interval  $[0, b_i]$
- Suppose we have  $k$  jumps
- Jump at  $z_1 = w_1$
- Jump at  $z_2 = w_2 - w_1$
- Jump at  $z_3 = w_3 - w_2$
- ...
- Jump at  $z_k = w_k - w_{k-1}$

# Myerson's lemma and payment formula

For most scenarios of interest

- The allocation is piecewise linear with multiple jumps
- The jump determines how many extra units the bidder wins

## Payment formula

- For each bidder  $i$  at a profile  $b$ , find all the jump points within  $[0, b_i]$
- $$p_i(b) = \sum_j z_j \cdot [\text{jump at } z_j]$$
$$= \sum_j z_j \cdot [w_j - w_{j-1}]$$
- The formula can also be generalized for monotone but not piecewise linear functions

# How does it work?

- For a fixed search term (e.g. *ipod*)
  - n advertisers
  - k slots (typically  $k \ll n$ )
  - An auction is run for every single search
  - Each advertiser (bidder) is interested in getting himself displayed in one of the slots
    - And usually they prefer a slot as high up as possible
  - Same auction is also run for related keywords (e.g. “buy ipod”, “cheap ipod”, “ipod purchase”, ...)
    - The advertiser can determine for which phrases to participate

# How does it work?

- Bidders submit an initial budget which they can refresh weekly or monthly
- Bidders also submit an initial bid which they can adjust as often as they wish
- The auction selects the winners to be displayed
- Different charging models exist: Pay Per Click, Pay Per Impression, Pay Per Transaction
- Currently, most popular is Pay Per Click
- A bidder is charged only if someone clicks on the bidder's ad

# The Actors

- The Search engine:
  - Wants to make as much revenue as possible
  - At the same time, wants to make sure users receive meaningful ads and bidders do not feel that they were overcharged
  - Big percentage of Google's revenue has been due to these auctions!
- The Bidders:
  - Want to occupy a high slot and pay as little as possible
- The Searchers:
  - Want to find the most relevant ads with respect to what they are looking for

# Analyzing sponsored search auctions

- We will focus on the bidders' side
- Model parameters for each bidder  $i$ 
  - Private information:  $v_i$  = maximum amount willing to pay per click = value/happiness derived from a click (private information)
  - Each bidder  $i$  submits a bid  $b_i$  for willingness to pay per click ( $b_i$  may differ from  $v_i$ )
  - We will ignore the budget parameter
    - In many cases, it is large enough and cannot affect the game
  - Hence, we have a single-parameter problem

# Analyzing sponsored search auctions

- We will focus on the bidders' side
- Model parameters for each slot  $j$ 
  - $\alpha_j$  = Click-through rate (CTR) of slot  $j$  = probability that a user will click on slot  $j$
  - Assume it is independent of who occupies slot  $j$ 
    - We can generalize to the case where the rates are weighted by a quality score of the advertiser who takes each slot
  - The search engines update regularly the CTRs and statistics show that
$$\alpha_1 \geq \alpha_2 \geq \alpha_3 \geq \dots \geq \alpha_k$$
  - Users tend to click on higher slots
    - Validation also by eye-tracking experiments

# Analyzing sponsored search auctions

- How shall we allocate the  $k$  slots to the  $n$  bidders?
- **Most natural allocation rule:** for  $i=1$  to  $k$ , give to the  $i$ -th highest bidder the  $i$ -th best slot in terms of CTR
  - Remaining  $n-k$  bidders do not win anything
- For convenience, assume that  $b_1 \geq b_2 \geq b_3 \geq \dots \geq b_n$
- Expected value of a winning bidder  $i$ :  $\alpha_i v_i$
- Is this rule monotone?
- Yes, bidding higher can only get you a better slot
- Hence we can apply Myerson's formula to find the payment rule
- For each bidder  $i$ , let  $x_i(b_i, b_{-i}) \in \{0, \alpha_k, \alpha_{k-1}, \dots, \alpha_1\}$

# Myerson's lemma for sponsored search auctions

- Let's analyze the highest bidder with bid  $b_1$
- Suppose we have 3 slots and  $n > 3$  bidders

- Look at the jumps of  $x_i$  in the interval  $[0, b_1]$
- Jump at  $b_4 = \alpha_3$
- Jump at  $b_3 = \alpha_2 - \alpha_3$
- Jump at  $b_2 = \alpha_1 - \alpha_2$

Total payment:

$$b_4 \alpha_3 + b_3 (\alpha_2 - \alpha_3) + b_2 (\alpha_1 - \alpha_2)$$

# Myerson's lemma for sponsored search auctions

- More generally, for the  $i$ -th highest bidder, there will be  $k-i+1$  jumps

$$p_i(\mathbf{b}) = \sum_{j=i}^k b_{j+1} [\alpha_j - \alpha_{j+1}]$$

- Under pay-per-click, no actual payment takes place at the end of every auction, unless there is a click by a user
- Need to scale so that expected per-click payment is  $p_i(\mathbf{b})$
- Proposed per-click payment to bidder in  $i$ -th slot:  $p_i(\mathbf{b})/\alpha_i$
- By Myerson, no other payment can achieve truthfulness with the same allocation rule

# Sponsored search auctions in practice

- In practice most engines do not use the payment of Myerson's lemma
- But they use the same allocation rule
- **The Generalized Second Price Mechanism (GSP)** - initial version:
  - The search engine ranks the bids in decreasing order:  
 $b_1 \geq b_2 \geq \dots \geq b_n$
  - The  $i$ -th highest bidder takes the  $i$ -th best slot
  - Every time there is a click on slot  $i$ , bidder  $i$  pays  $b_{i+1}$
  - There is also a reserve price (opening bid), initially the same for every keyword (\$0.1), later became keyword-dependent

# The Generalized Second Price Mechanism (GSP)

- A better version:
  - The search engine keeps a quality score  $q_i$  for each bidder  $i$ 
    - Yahoo, Bing (till a few years ago):  $q_i$  is the click-through rate of  $i$  (probability of a user clicking on an ad of bidder  $i$ )
    - Google:  $q_i$  depends on click-through rate, relevance of text and other factors
  - The search engine ranking is in decreasing order of  $q_i \times b_i$   
 $q_1 \times b_1 \geq q_2 \times b_2 \geq \dots \geq q_n \times b_n$
  - The first  $k$  bidders of the ranking are displayed in the  $k$  slots
  - Every time there is a click on slot  $i$ , bidder  $i$  pays the minimum bid required to keep his position, i.e.  $(q_{i+1} \times b_{i+1}) / q_i$

$$q_i \times x_i \geq q_{i+1} b_{i+1} \Rightarrow x_i \geq \frac{q_{i+1} b_{i+1}}{q_i}$$

# The Generalized Second Price Mechanism (GSP)

- Myerson's lemma implies GSP cannot be truthful
  - Otherwise, its payment rule would coincide with the Myerson formula
- The deployment of GSP was probably just an educated guess
  - As an attempt to generalize the Vickrey auction and use something simple that looked close to truthful!
- Nevertheless...
  - For a long period, revenue from GSP was 95% of Google's revenue
  - Still nowadays an important percentage of search engines' revenue
- Theoretical analysis of GSP: later in this lecture

# Multi-unit auctions

# Multi-unit Auctions

Auctions for selling multiple identical units of a **single good**

In practice:

- US Treasury notes, bonds
- UK electricity auctions (output of generators)
- Spectrum licences
- Various online sales

# Multi-unit Auctions

## Online sites offering multi-unit auctions

- US
  - [www.onlineauction.com](http://www.onlineauction.com)
- UK
  - [uk.ebid.net](http://uk.ebid.net)
- Greece
  - [www.ricardo.gr](http://www.ricardo.gr)
  - Actually not any more...
- ...

# Some Notation

- $n$  bidders
- $k$  available units of an indivisible good
- Bidder  $i$  has valuation function  $v_i : \{0, 1, \dots, k\} \rightarrow \mathbb{R}$ 
  - $v_i(j)$  = value of bidder  $i$  for obtaining  $j$  units
- Representation with marginal valuations:
  - $m_i(j) = v_i(j) - v_i(j-1)$  = additional value for obtaining the  $j$ -th unit, if already given  $j-1$  units
  - $(m_i(1), m_i(2), \dots, m_i(k))$ : vector of marginal values

# Some Valuation Classes

- In the multi-unit setting, a valuation  $v_i$  is *submodular* iff
$$\forall x \leq y, \quad v_i(x + 1) - v_i(x) \geq v_i(y + 1) - v_i(y)$$
  - Hence:  $m_i(1) \geq m_i(2) \geq \dots \geq m_i(k)$  (decreasing marginal values)
- A valuation  $v_i$  is *subadditive* iff
$$\forall x, y, \quad v_i(x + y) \leq v_i(x) + v_i(y)$$
- In many multi-unit auctions, bidders are asked to submit a submodular valuation
  - Makes sense due to the saturation of getting more and more units
- **Valuation compression:** Even if bidders are not submodular, they would still have to express their preferences by a submodular function

# A Bidding Format for Multi-unit Auctions

- Used in various multi-unit auctions

[Krishna '02, Ch. 12-13, Milgrom '04, Ch. 7]

1. The auctioneer asks each bidder to submit a vector of decreasing marginal bids
  - $\mathbf{b}_i = (b_i(1), b_i(2), \dots, b_i(k))$
  - $b_i(1) \geq b_i(2) \geq \dots \geq b_i(k)$
2. The bids are ranked in decreasing order and the  $k$  highest win the units

Simplified format in some cases: Uniform bidding, i.e., ask for a bid per unit + number of units demanded

# Example

$$\mathbf{b}_1 = (45, 42, 31, 22, 15)$$

$$\mathbf{b}_2 = (35, 27, 20, 12, 7)$$

$$\mathbf{b}_3 = (40, 33, 24, 14, 9)$$

How should we charge the winners?

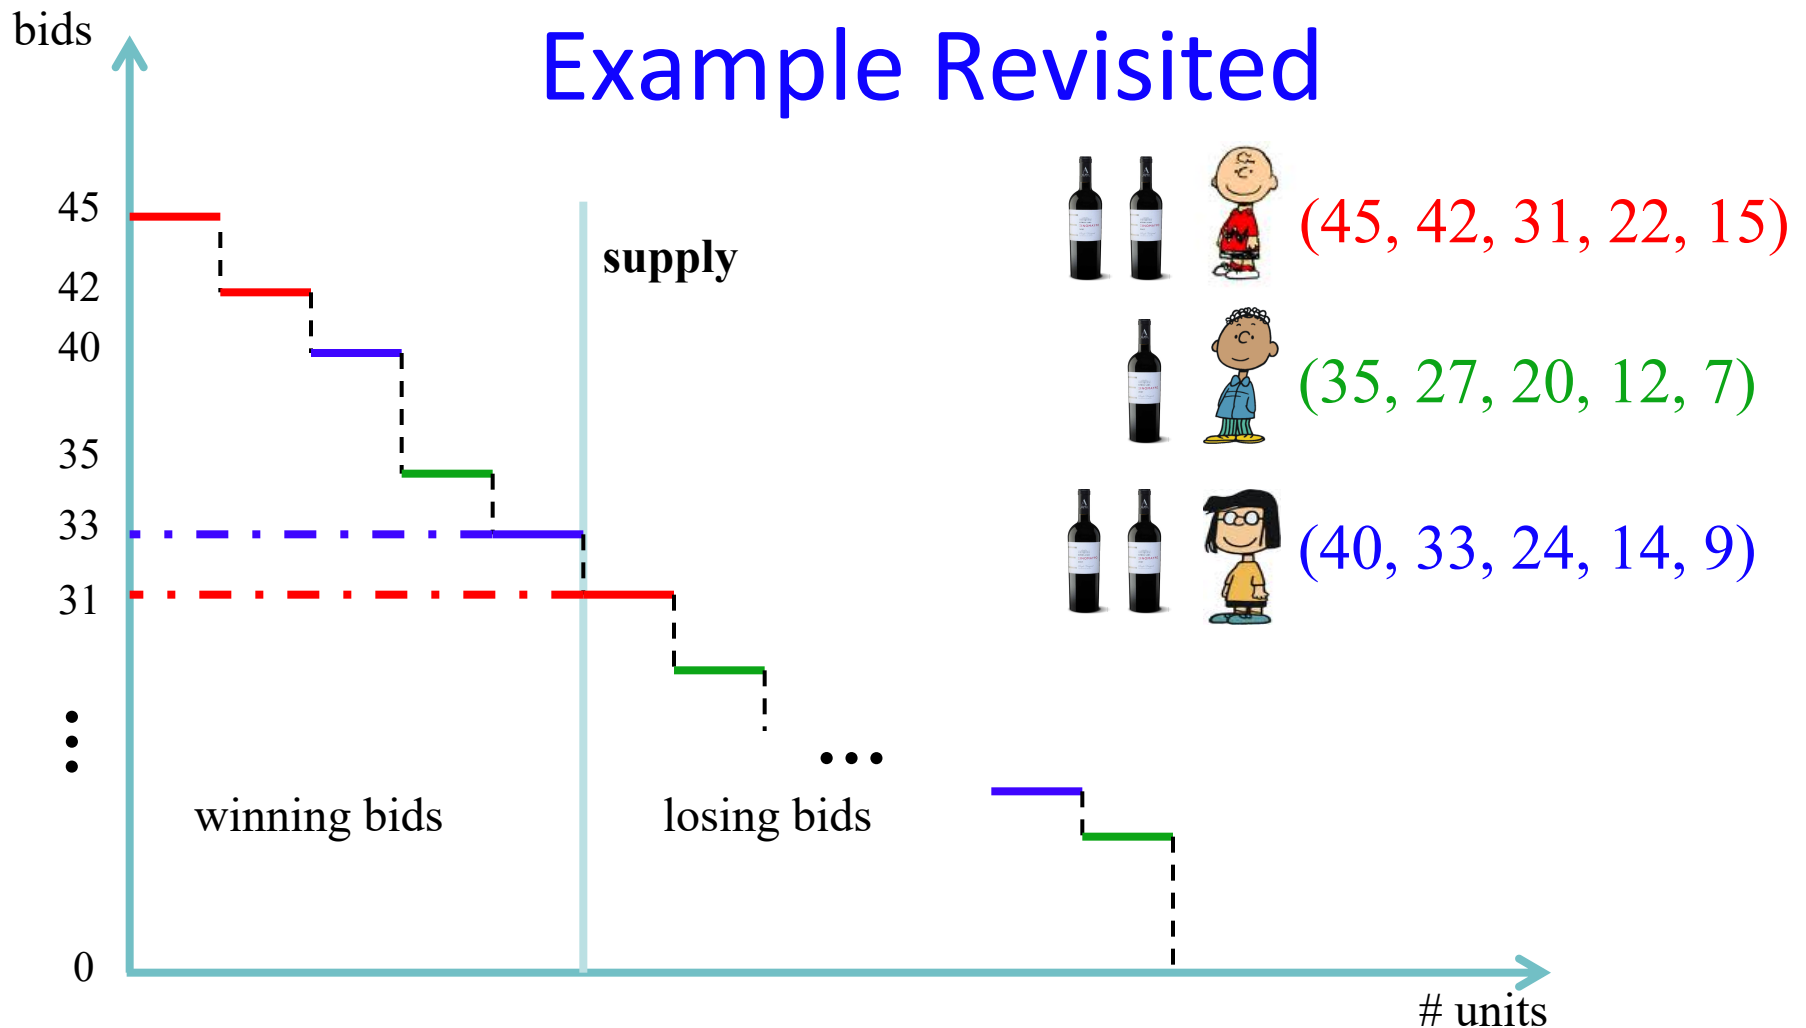

# Pricing Rules

1. Multi-unit Vickrey auction (VCG) [Vickrey '61]
  - Each bidder pays the externality he causes to the others
  - Generalization of single-item 2<sup>nd</sup> price auction
  - Good theoretical properties, truthful, but barely used in practice
2. Discriminatory Price Auction (DPA)
  - Bidders pay their bids for the units won
  - Generalization of 1<sup>st</sup> price auction
  - Not truthful, but widely used in practice

## Pricing Rules (cont' d)

3. Uniform Price Auction (UPA) [Friedman 1960]
  - Same price for every unit
  - Interval of prices to pick from:  
[highest losing bid, lowest winning bid]
  - This lecture: price = highest losing bid
  - For 1 unit, same as Vickrey auction
  - For  $\geq 2$  units, not truthful, but widely used in practice  
(following the campaign of Miller and Friedman in the 90' s)

# Example Revisited

Interval of candidate prices for UPA =  $[31, 33]$

Uniform price = 31

# Uniform Price vs Discriminatory?

- Debate still going on for treasury auctions
- DPA is thought to raise more revenue (no formal justification though)
- UPA eliminates complaints arising from price discrimination (identical goods should cost the same!)

# **Equilibrium analysis of non-truthful mechanisms**

# Non-truthful mechanisms

- As already seen, there are plenty of settings where the mechanism employed is not truthful
  - Sponsored search
  - Auctions for government bonds
  - Some types of auctions for telecom/spectrum licences (e.g., core-selecting auctions)
- Why?
  - Low revenue often achieved by truthful auctions, e.g., by VCG
  - Complexity: Social welfare maximization may turn out too difficult to solve (which is a required step in VCG-based mechanisms)
- [Ausubel, Milgrom '06]: The lovely but lonely Vickrey auction
  - Chapter 1 in the book “Combinatorial Auctions”

# Non-truthful mechanisms

- How do we evaluate non-truthful mechanisms?
  - If the bidders are non-truthful, can we argue about the social welfare generated?
- We can think of the equilibria as the most likely outcomes to occur
  - If these games are played frequently, players may end up at an equilibrium by adjusting gradually their strategies
  - Thus, we can take the social welfare or revenue achieved at an equilibrium as an evaluation metric

# PoA in auctions

- Consider an auction where  $v_i$  = actual valuation function of bidder  $i$ 
  - It can be either single or multi-parameter
- Let  $\mathbf{b}$  be a pure Nash equilibrium with resulting allocation:  
 $(x_1, \dots, x_n) = (x_1(\mathbf{b}), \dots, x_n(\mathbf{b}))$
- Social Welfare at  $\mathbf{b}$ :  $SW(\mathbf{b}) = \sum v_i(x_i)$
- $OPT$  = Optimal welfare (as determined by the valuations)

$$PoA = \sup_{\mathbf{b}} OPT/SW(\mathbf{b})$$

Where the supremum can be either over all pure or over all mixed equilibria

# PoA in sponsored search auctions

- PoA can become unbounded in worst case
- [Lahaie '06 ]:  $\text{PoA} \leq (\min_{1 \leq i \leq k-1} \min\{\alpha_{i+1}/\alpha_i, 1 - (\alpha_{i+2}/\alpha_{i+1})\})^{-1}$ 
  - For pure equilibria, when we have  $k \geq 2$  slots
  - Where recall  $\alpha_i$  is the CTR of slot  $i$ , and assume  $\alpha_{k+1} = 0$
- For arbitrary auctions, the ratios of the CTRs can become arbitrarily high
- In some cases, the click data fit well with an exponential decay model (geometric CTRs):  $\alpha_i \propto 1/\delta^i$  for a constant  $\delta$ 
  - [Feng, Bhargava, Pennock '07]:  $\delta = 1.428$  using various empirical datasets
  - In these cases,  $\text{PoA} \leq (\min\{1/\delta, 1-1/\delta\})^{-1}$
  - Hence, low inefficiency under geometric CTRs

# PoA in sponsored search auctions

- One can also study PoA under restrictions on the set of equilibria under consideration
- E.g., some “bad” equilibria arise when some players overbid and at the same time some high-valued players underbid
- **The no-overbidding assumption:** Focus on equilibria where  $b_i \leq v_i$ 
  - Such bidders are also referred to as conservative bidders
  - Initiated in [Christodoulou, Kovacs, Schapira '08], and assumed in several follow up works
- Can PoA be better under no-overbidding?

# PoA in sponsored search auctions

- [Paes Leme, Tardos '10]: Under no-overbidding
  - $\text{PoA} \leq 1.618 (= 1 + \phi)$  for pure equilibria
  - $\text{PoA} \leq 4$  for mixed equilibria
- [Lucier, Paes Leme '11, Caragiannis et al. '11, '15]:  
Currently best known:
  - $\text{PoA} \leq 1.28$  for pure equilibria
  - $\text{PoA} \leq 2.31$  for mixed equilibria
- For lower bounds, it is known that  $\text{PoA} \geq 1.259$
- **Main conclusion:** For conservative bidders, selfish behavior does not lead to socially bad outcomes

# Revenue in sponsored search auctions

- Could we have analogous guarantees for revenue instead of social welfare?
  - Harder problem...
- But, some comparisons can be drawn between the use of GSP and VCG
- [Varian '05, Edelman, Ostrovsky, Schwarz '07]: Focus on the class of “locally envy-free equilibria”
  - As a plausible class of equilibria that may arise
  - Analyzed for the simple version of GSP, without the personalized quality score  $q_i$
  - But their results can be stated for the more general setting as well

# Revenue in sponsored search auctions

- For convenience, rename the bidders so that the bidder occupying slot  $j$  has value  $v_j$  and pays price  $p_j$ 
  - i.e.,  $p_j = \text{bid of bidder in slot } j+1$

- **Definition:** The profile  $\mathbf{b} = (b_1, b_2, \dots, b_n)$  is a **locally envy-free equilibrium**, if for a bidder at slot  $s$ , we have

$$\alpha_s (v_s - p_s) \geq \alpha_j (v_s - p_j) \text{ for every other slot } j$$

- This means no bidder is willing to swap her slot and price with those of another bidder
- In fact, it suffices to check only the neighboring slots
  - Look only at slot  $s-1$  and  $s+1$  for the bidder at slot  $s$
  - Thus the name “locally envy-free”

# Revenue in sponsored search auctions

- Main theorem in [Varian '05, Edelman, Ostrovsky, Schwarz '07]:
  - (i) There exists a no-overbidding locally envy-free equilibrium where allocation + payments coincide with the VCG outcome
  - (ii) The revenue at any locally envy-free equilibrium  $\geq$  VCG revenue (at truthful profile)
- Can be seen as a justification of why GSP is a better choice than VCG for sponsored search auctions
- Although GSP was probably employed by accident, it was a rather good choice!

# PoA in multi-unit auctions

- A PoA analysis can be carried out for any other non-truthful auction
- For multi-unit auctions, PoA can be affected by the phenomenon of “demand reduction”
  - [Ausubel, Cramton '96]: Bidders may have incentives to hide their demand for items in order to achieve a better price

# Example of Demand Reduction in UPA

Real profile

Equilibrium profile

$OPT = 3, SW(\mathbf{b}) = 13/6 \Rightarrow PoA \geq 18/13$  for UPA

- Revealing the true profile for bidder 1 results in a relatively high price
- Demand reduction discussed further in [Ausubel, Cramton '96]

# PoA for pure equilibria

Can demand reduction create a huge loss of efficiency?

**Theorem:**

For the Discriminatory Price Auction (DPA), and **arbitrary** monotone valuations for the bidders, **PoA = 1**

- No need to assume no-overbidding
- All pure Nash equilibria (when they exist) are efficient
- Generalizes what holds for the single-item 1<sup>st</sup> price auction (recall your first homework!)
- Existence of pure equilibria guaranteed under appropriate tie-breaking rules

# PoA for pure equilibria

- The same is not true for UPA
- **Example:** Consider  $k$  units and the profiles:

Real profile

$(k, 0, 0, \dots, 0)$

$(1, 1, 1, \dots, 1)$

Equilibrium profile **b**

$(1, 1, 1, \dots, 1)$

$(0, 0, 0, \dots, 0)$

- $OPT = 2k-1$
- $SW(\mathbf{b}) = k$
- $PoA \geq (2k-1)/k = 2 - 1/k$  for UPA
- Can it get worse?

# PoA for pure equilibria

- For non-conservative bidders, it can get unbounded
- The no-overbidding assumption in UPA:

$$\sum_{j=1}^s b_i(j) \leq v_i(s) \quad \forall i, \forall s \leq k$$

[Birmpas, Markakis, Telelis, Tsikiris '17]:

For the Uniform Price Auction (UPA), and for

- Submodular bidders
- No-overbidding pure equilibria,

$$\text{PoA} \leq 2.18$$

- Tight example even for 2 bidders

# PoA for mixed equilibria

[de Keijzer, Markakis, Schaefer, Telelis '13]:

For submodular valuations, the PoA for mixed equilibria is

- $\leq e/e-1$  for DPA
- $\leq 3.146 < 2e/e-1$  for UPA

## Remarks:

- $3.146... = |W_{-1}(-1/e^2)|$  (Lambert W function)
- Bounds hold both for standard bidding and for the simplified uniform bidding format
- The same bounds also hold for Bayesian games (PoA for Bayes-Nash equilibria)

# PoA for mixed equilibria

- Currently known lower bounds:  $\approx 1.1$  for DPA, 2.18 for UPA
  - Far from tight in the case of mixed equilibria
- Our proof can be cast into the smoothness framework of [Syrgkanis, Tardos '13]

- Upper bounds carry over to simultaneous and sequential compositions of multi-unit auctions (e.g. combinatorial multi-unit auctions)
- Similar approaches and techniques used in other types of auctions as well (e.g. item-bidding auctions)  
[Christodoulou, Kovacs, Schapira '08, Bhawalkar, Roughgarden '11, Feldman, Fu, Gravin, Lucier '13]

# Beyond Submodular Valuations

- [Milgrom '04]: Very little known (i.e., nothing) for non-submodular bidders
- Subadditive valuations: Valuation compression is needed for such bidders

**Lemma:** Subadditive valuations can be approximated by submodular functions, losing a factor of 2

# Subadditive Valuations

**Theorem:** For subadditive valuations, mixed PoA is at most:

Auction \ Bidding	Standard bidding	Uniform bidding
DPA	2	$2e/e-1$
UPA	4	$6.292 < 4e/e-1$

- Uniform bidding: same technique as before, using the 2-approximation
- Standard bidding: Adaptation of [Feldman, Fu, Gravin, Lucier '13] into multi-unit auctions
  - Deviation constructed by sampling from the distribution of  $\mathbf{b}_i$

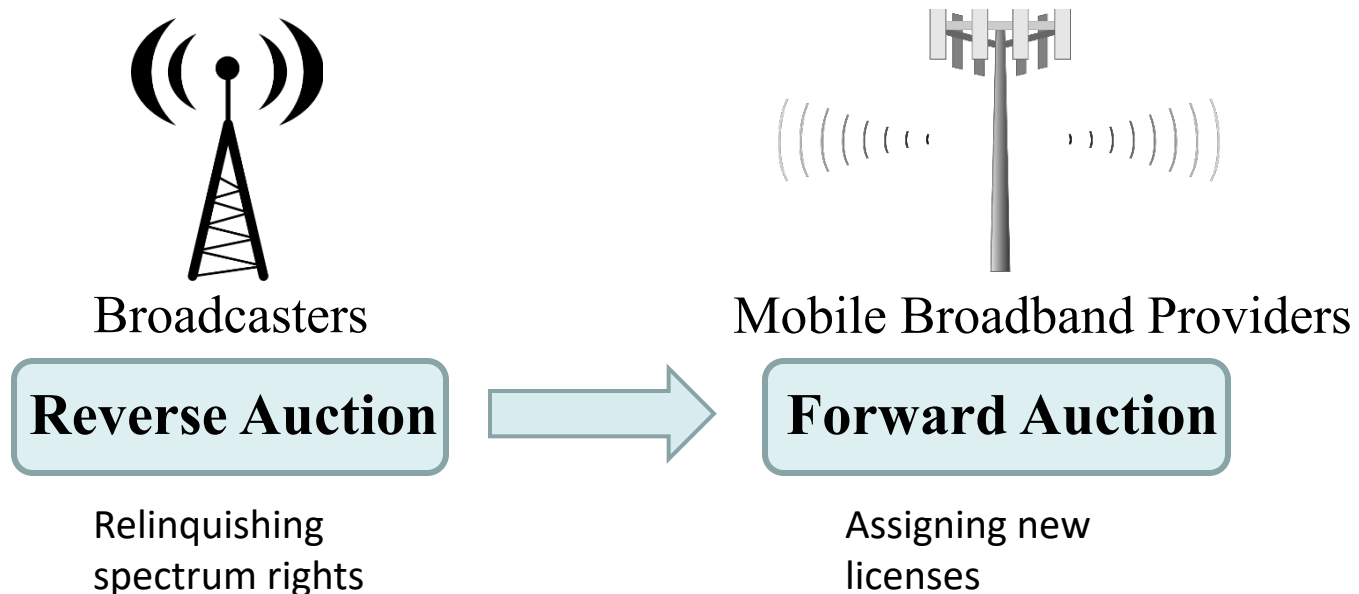

# Conclusions on PoA

- **Take-home story:** simple auction formats used in practice perform quite well w.r.t. social welfare
- Upper bounds:
  - For pure equilibria, almost tight for sponsored search, completely tight for multi-unit auctions
  - Open if we can improve the bounds for mixed equilibria
  - PoA can also become even better if we focus on Nash equilibria in undominated strategies
- Lower bounds:
  - Much harder to get

# **Examples of truthful auctions in practice**

# Spectrum Auctions

- Deferred Acceptance Auctions initiated by [Milgrom, Segal '14]
- Motivated by the design of the FCC “**Broadcast Incentive Auction**”

- Commenced on March 2016, closed on April 2017 for repurposing spectrum to align with consumer demand for broadband services

# Basic Mechanism Design Setting

## Main features:

- A **provider** of some service or resources
- A set of **single-parameter buyers**  $N = \{1, 2, \dots, n\}$  interested in (some of) the resources
- Each buyer has a **valuation**  $v_i$
- For each buyer: need to make an **accept/reject** decision
- **Feasible solutions:** Only specific subsets of buyers may be served simultaneously, due to problem constraints (e.g. interference constraints in spectrum auctions)

# The framework of Deferred-Acceptance Auctions

- Backward greedy allocation algorithms
- They work in rounds, finalizing the decision for a single bidder in each round
- $A_t$  = set of active bidders at round  $t$
- Score of bidder  $i$  at round  $t$ :  $\sigma_i^{A_t}(b_i, b_{N \setminus A_t})$ 
  - non-decreasing in  $b_i$
  - Possible dependence on the set  $A_t$  (but not on the bids of active bidders)

1. Initially all bidders are **active** ( $A_1=N$ )
2. While accepting all active bidders in  $A_t$  is **infeasible**
  - **Reject** the bidder  $i$  with the lowest score
  - $A_{t+1} = A_t \setminus \{i\}$
3. Remaining bidders are **accepted** and pay **threshold prices**

# Properties of Deferred-Acceptance Auctions

## Incentive guarantees:

- Not hard to show that DA auctions are truthful
- In fact we can have much stronger incentive guarantees

**Definition:** A mechanism is **weakly group-strategyproof** if: for any coalition  $S \subseteq N$ , and any profile  $b_{-S}$ , there is no deviation by  $S$ , such that all members are strictly better off, i.e., such that:

$$u_i(b_S, b_{-S}) > u_i(v_S, b_{-S}), \text{ for every } i \in S$$

**Lemma:** DA auctions are weakly group-strategyproof

# Properties of Deferred-Acceptance Auctions

## Further advantages of DA auctions:

1. Practical and simple to implement **as long as**
  - Scoring function is simple
  - Checking feasibility of a solution is easy
2. They admit an implementation as an ascending clock auction
3. Using the ascending auction implementation:
  - Very easy to argue that truth-telling is a dominant strategy (**obvious strategyproofness** [Li '15])
  - Privacy preservation: winners do not reveal their true value

## Possible limitations:

1. They do not always guarantee a good approximation to the social welfare
2. Same for other objectives (e.g. revenue)
3. Solution returned may not be a maximal set w.r.t. problem constraints (drawback of backward greedy algorithms)

# An illustration

Recall single-minded bidders from previous lectures

- The auctioneer has a set  $M$  of items for sale
- Each bidder  $i$  is interested in acquiring a specific subset of items,  $S_i \subseteq M$  (known to the mechanism)
  - If the bidder does not obtain  $S_i$  (or a superset of it), his value is 0
- Each bidder submits a bid  $b_i$  for his value if he obtains the set
- Motivated by certain spectrum auctions
- Feasible allocations: the auctioneer needs to select winners who do not have overlapping sets

# Single-minded bidders

## Examples

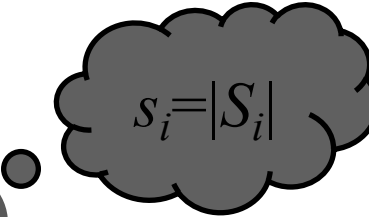

- In the example above, the auctioneer can accept only 1 bidder as a winner
- In the example below, the auctioneer can accept up to 2 bidders as winners

# A forward greedy algorithm for single-minded bidders

[Lehmann, O' Callaghan, Shoham '01]:

- Order the bidders in decreasing order of  $b_i/\sqrt{s_i}$
- Accept each bidder in this order unless overlapping with previously accepted bidders

$$s_i = |S_i|$$

This algorithm achieves

- Monotonicity of the allocation (hence can be made truthful)
- $1/\sqrt{m}$ -approximation, where  $m = |M|$
- $1/d$ -approximation, where  $d = \max_i s_i$

**Final conclusion:** truthful polynomial time mechanism with the best possible approximation to the social welfare

# Coalitions under the forward greedy mechanism

- The forward greedy mechanism is truthful but suppose players could also collude:

- What would forward greedy do?
  - Accept bid  $\{c, d\}$
  - Reject bids  $\{a, c\}$  and  $\{b, d\}$
  - Accept bid  $\{a, b\}$
  - Threshold price = 0
- The coalition  $\{3, 4\}$  can change the outcome
- Threshold price still 0
- Both members better off!
- Forward greedy is not group-strategyproof

# Scoring Functions for DA auctions

- Can we achieve similar welfare guarantees with backward greedy algorithms?
- How about a DA auction with scoring  $\sigma_i(v_i, s_i) = v_i / \sqrt{s_i}$  ?

- Backward greedy can do much worse than forward greedy
- Use conflict number  $\sigma_i(v_i, c_{i,t}) = v_i / c_{i,t}$  ?
  - $c_{i,t}$  = number of conflicts with other bidders at stage t

[Dutting, Gkatzelis, Roughgarden '14]:

- This does not work either
- Having  $s_i$  or  $c_{i,t}$  in the denominator, raised to any power cannot achieve an  $O(1/d)$  or  $\tilde{O}(1/\sqrt{m})$  approximation

# Positive results for DA auctions

[Dutting, Gkatzelis, Roughgarden '14]:

**Theorem 1:** There exists a DA auction that achieves an approximation ratio of  $O(d)$

**Theorem 2:** There exists a DA auction that achieves an approximation ratio of  $O(\sqrt{m} \log m)$

**Main message:**

We can have comparable approximations as in forward greedy, but with stronger incentive guarantees!

- And with a more complicated scoring function

# Final conclusions

- A wide range of applications
- The full spectrum of incentive guarantees can be seen in practice
  - **Non-truthful and bad equilibria** (uniform price auction or sponsored search with overbidding)
  - **Non-truthful and efficient equilibria** (single-item first price auction)
  - **Non-truthful and relatively efficient equilibria** (sponsored search, uniform price auction, under no-overbidding)
  - **Truthful** (single-item Vickrey)
  - **Weakly group-strategyproof** (DA auctions)
- The choice of mechanism deployed may depend on:
  - Traditions and practices used in a specific application domain (not always easy to switch to a new format)
  - Complexity considerations (simplicity is often a must)
  - Legal issues (there exist governmental auctions where social welfare w.r.t. reported bids needs to be maximized)
